Most games violate the common priors doctrine

Yaw Nyarko*

The type of a player in a game describes the beliefs of that player about the types of others. We show that the subset of vectors of such player-type beliefs which obey the consistency condition sometimes called the Harsanyi doctrine is of Lebesgue measure zero. Furthermore, as the number of players becomes large the ratio of the dimension Harsanyi-consistent beliefs to the set of all beliefs tends to zero.

1 Introduction

Consider a game with $N$ players each of whom is one of a finite number of types. The type of a player describes the beliefs that a player-type has about the types of the other players. A belief system is a specification of the beliefs of each player-type. A belief system is said to be consistent if there exists a probability measure, $\pi$, over the set of vectors of all types such that each player-type’s beliefs equal the probability measure $\pi$ conditional on that type. This consistency requirement is typically referred to as the “Harsanyi doctrine” of Harsanyi (1968). Harsanyi (1968) argues that all differences in beliefs of players must be due to differences in the information they have received and, hence, players must necessarily have consistent belief systems.

In a Harsanyi consistent game the type of a player fulfills two roles: first, it specifies the beliefs of that player about the types of the others; and, second, it provides the signal used in conditioning the joint probability, $\pi$, to obtain beliefs about other agents. The beliefs obtained via these two roles must be the same. The results of the present paper show that this places a lot of restrictions on the belief systems possible, and, in particular most of them cannot fulfill both roles simultaneously.

Let $B$ denote the set of all belief systems and let $H$ denote the subset of $B$ that obeys the Harsanyi doctrine. I show that the dimension of $H$ is much lower than that of the set $B$ and, hence, the set $H$ has Lebesgue measure zero in $B$. Among the set of all belief systems,

I thank my teacher Professor Tapan Mitra for his inspiration and guidance over the years, and I congratulate him on his 60th birthday – may he have many more birthdays. I thank Professors Roy Radner and Chuck Wilson for many helpful suggestions. The support of the C.V. Starr Center and the Research Challenge Fund at New York University is gratefully acknowledged.
most of them violate the Harsanyi doctrine. I also show that relative to the dimension of $B$ the dimension of $H$ becomes arbitrarily small as the number of players tends to infinity.

That a belief system can violate the Harsanyi doctrine is well-known among researchers in this area (see e.g. Mertens and Zamir 1985). However, to the best of my knowledge, this result on the size of the set of belief systems that violate the Harsanyi Doctrine is new.\footnote{Very recently, and long after the first working paper versions of this paper, Hellman and Samet (2009) considered a similar question in the context of generalized partitional knowledge spaces.} The result itself, once the problem has been set up to answer the appropriate question, is embarrassingly easy to prove, and involves counting the dimensionality of certain sets.

The question that is being asked reduces to the following: When does there exist a joint probability measure with given conditional distributions? Our answer is: almost never. (This is of course not to be confused with the question of the the existence of a joint distribution with given marginals [see e.g. Strassen 1965]).

One often hears the argument that if one adds some extra states or passive agents to the game one can transform any game into one for which the Harsanyi doctrine holds. The setup of this paper should show that this is not possible if such a transformation is done properly.

The Harsanyi doctrine is of course is an assumption often used in many papers in game theory and in other applied fields like industrial organization theory. Elsewhere we have argued that the use of the Harsanyi doctrine may be very restrictive in models of learning (see Nyarko 1990).

2 An illustration for the $2 \times 2$ case

Suppose there are two Players A and B. Player A can be one of two types $a_1$ or $a_2$, and Player B can be one of two types $b_1$ or $b_2$. Conditional upon each player’s type, that player will have beliefs about the types of the other player. Because each player can only be one of two types, each player’s beliefs about the other is a number in $[0, 1]$ representing the probability that player assigns to the other player being of the first type.

In particular, Player A’s belief system is a pair $p = (p_1, p_2) \in [0, 1]^2$, and Player B’s is a pair $q = (q_1, q_2) \in [0, 1]^2$, with the following interpretation:

\[ p_i = \text{Prob} \left( b_j \mid a_i \right) \quad \text{and} \quad q_i = \text{Prob} \left( a_i \mid b_j \right) \quad \text{for } i = 1, 2. \tag{1} \]

The set of all beliefs systems, $(p, q)$, is the set $B = [0, 1]^4$. If these beliefs are to obey the Harsanyi doctrine there must exist a joint probability measure $\pi = \{\pi_{ij}\}_{i,j=1}^2$ over the four pairs of possible types $\{(a_1, b_1), (a_1, b_2), (a_2, b_1), (a_2, b_2)\}$, where $\pi_{ij}$ denotes probability assigned to the vector $(a_i, b_j)$ by the probability $\pi$, such that each player’s beliefs are obtained via conditioning $\pi$ on that player’s own realized type (i.e. such that $p_i = \pi \left( b_j \mid a_i \right)$ and $q_i = \pi \left( a_i \mid b_j \right)$ for $i = 1, 2$).

I will restrict attention to strictly interior belief systems; that is, where $(p, q) \in (0, 1)^4$. In that case, if a probability $\pi$ with the abovementioned properties does exist, then from
Bayes’ rule we know that such a probability must satisfy the following relationships:

\[
\sum_{i, j} \pi_{ij} = 1 \quad \text{where the sum is over } i, j = 1, 2
\]  

(2)

\[
p_1 = \frac{\pi_{11}}{\pi_{11} + \pi_{12}}
\]  

(3)

\[
p_2 = \frac{\pi_{21}}{\pi_{21} + \pi_{22}}
\]  

(4)

\[
q_1 = \frac{\pi_{11}}{\pi_{11} + \pi_{21}}
\]  

(5)

\[
q_2 = \frac{\pi_{12}}{\pi_{12} + \pi_{22}}.
\]  

(6)

Observe that in the above system of equations, if we consider the vector \((p, q)\) as given, then there are four unknowns, \([\pi_{ij}]_{i, j=1}^2\) and five equations. This system of equations is overidentified and, in general, the system of equations will not have a solution. Indeed, from (3)–(6) it is easy to verify that

\[
q_2 = \left[\frac{(1 - p_1) / p_1}{[(1 - p_1) / p_1] + [(1 - p_2) / p_2] [(1 - q_1) / q_1]}\right].
\]  

(7)

Equation (7) requires that \(q_2\) be an (explicit) function of \((p_1, p_2, q_1)\). The subset of vectors \((p_1, p_2, q_1, q_2)\) in the unit simplex in \(R^4\), which are Harsanyi consistent, necessarily satisfy (7) and, therefore, lie in a three dimensional subset of \(R^4\).

### 3 The general problem

Now suppose there are \(N\) players, \(i = 1, \ldots, N\). Each player can be one of a finite number of types, \(c_{ik} \in C_i\), for \(k = 1, \ldots, \#C_i\), where \(\#C_i\) is the cardinality of of the set \(C_i\). Let \(C = \bigcup_{i=1}^{N} C_i\) denote the set of all possible vectors of types, one for each player, and let \(C_{-i} = \bigcup_{j \neq i} C_j\) denote the set of vectors of types of all players other than the \(i\)th player. Given any finite integer \(T\) let \(\Delta(T)\) denote the \((T - 1)\) dimensional unit simplex in \(R^T\), and let \(\Delta(T)^+\) denote the strictly positive subset of \(\Delta(T)\):

\[
\Delta(T) = \left\{ x = (x_1, \ldots, x_T) \in R^T \mid \sum_{t=1}^{T} x_t = 1 \quad \text{and} \quad x_t \geq 0 \quad \text{for all } t \right\}
\]  

and

\[
\Delta(T)^+ = \left\{ x = (x_1, \ldots, x_T) \in \Delta(T) \mid x_t > 0 \quad \text{for all } t \right\}.
\]  

(7)

Associated with the \(k\)th type of the \(i\)th player, \(c_{ik}\), is the belief that player has about the types of the other players. This will be a probability measure, \(p_{ik}\), on \(C_{-i}\); in particular, \(p_{ik} \in \Delta(\#C_{-i})\). A belief system for the players is a specification of such a vector \(p_{ik}\) for each
player $i$, and for each type of player $i$, $c_{ik}$. We let $B$ denote the set of all belief systems and let $B^+$ be the subset of belief systems in $B$ that are strictly positive; that is,

$$B = \prod_{i=1}^{N} X_{c_{ik} \in C_i} \Delta (\#C_{-i}) \quad \text{and} \quad B^+ = \prod_{i=1}^{N} X_{c_{ik} \in C_i} \Delta (\#C_{-i})^+. \quad (8)$$

Recall that $C = \prod_{i=1}^{N} C_i$ is the set of all player types. Let $G$ be the set of all probability measures over $C$ and let $G^+$ be the subset of $G$ that are strictly positive:

$$G = \Delta(\#C) \quad \text{and} \quad G^+ = \Delta(\#C)^+. \quad (9)$$

For a belief system of players, $p \in B$, to be consistent in a Harsanyi (1968) sense and, hence, to obey the “Harsanyi doctrine,” there must exist a probability measure $\pi \in G$ on the set of all possible vectors of types of players, $C$, from which the beliefs of each player of each type is obtained by conditioning on their own types; that is, $p_{ik} = \pi(. \mid c_{ik})$ for each player $i$ and type $c_{ik}$, where $\pi(. \mid c_{ik})$ denotes the conditional probability of $\pi$ conditional on $c_{ik}$. Because the set of types are finite, the conditional probabilities can be obtained using Bayes’ rule.

Indeed, fix any belief system $p \in B$ and probability measure over types, $\pi \in G$. Let $p_{ik}(c_{-i})$ and $\pi(c)$ denote the probability assigned to $c_{-i} \in C_{-i}$ and $c \in C$ by $p_{ik}$ and $\pi$, respectively. Let $\{c_{-i}, c_{ik}\}$ denote the element of $C$ whose $i$th coordinate is $c_{ik}$ and whose other coordinates are the vector $c_{-i}$; and let $\pi(c_{ik})$ be the probability assigned by $\pi$ to the event that the $i$th player’s type is $c_{ik}$.

For a belief system $p \in B$ to be consistent we require the existence of a probability $\pi \in G$ that obeys Bayes’ rule: For each $i = 1, \ldots, N$, for each $c_{ik} \in C_i$ such that $\pi(c_{ik}) > 0$, and for each $c_{-i} \in C_{-i}$,

$$p_{ik}(c_{-i}) = \pi(\{c_{-i}, c_{ik}\})/\pi(c_{ik}). \quad (10)$$

Now, each vector in $\Delta(\#C_{-i})$ is a vector in a $(\#C_{-i} - 1)$-dimensional space. Hence, from (8), the set $B$ is a set of vectors of dimension

$$\dim B = \sum_{i=1}^{N} (\#C_i)(\#C_{-i} - 1) = NX_{i=1}^{N} (\#C_i) - \sum_{i=1}^{N} (\#C_i). \quad (11)$$

Because we are primarily concerned with dimensionality calculations we may restrict our attention to strictly positive belief systems; that is, those in $B^+$ and $H^+$, and strictly positive joint probability vectors (in $G^+$). Now each probability $\pi \in G^+$ induces a unique belief system $b(\pi)$ in $H^+$ via Bayes’ rule, (10). It is easy to check that this mapping $b:G^+ \to H^+$ is continuous on $G^+$. From the definition of $H^+$, for each $p \in H^+$, there exists a $\pi \in G$ such that $b(\pi) = p$; it is easy to check that if $p$ is strictly positive, that is, $p \in H^+$, then so is $\pi$ so that the mapping $b:G^+ \to H^+$ is ONTO.

Next, if $p \in H^+$, then $p$ is an indecomposable belief system in the sense of Harsanyi (1968, Theorem III) and, therefore, from that theorem there can only be one probability $\pi \in G$ that induces it (i.e. such that $b(\pi) = p$). In particular, the mapping $b:G^+ \to H^+$ is ONE-TO-ONE. It is also easy to check that the mapping $b:G^+ \to H^+$ is differentiable.
Hence, we may identify the set $G^+$ with $H^+$ in the dimensionality calculations and, in particular, we may set

$$\dim H = \dim G = \#C - 1 = \left[ X_N^N (\#C_i) \right] - 1$$  \hspace{1cm} (12)

(e.g. via applications of Sard's Theorem).\(^2\)

Of course, without loss of generality we may suppose that there are at least two players and that each player has at least two possible types, so that $\#C_i \geq 2$ for all $i$. With (11) and (12) we may now very easily state and prove our main result (which follows immediately from Lemma 1 in the Appendix).

**Proposition 1**  
(a) Fix the number of players $N \geq 2$. Then $\dim H < \dim B$ and, in particular, the subset $H$ of Harsanyi consistent belief systems has Lebesgue zero in the set $B$ of all belief systems.

(b) As the number of players $N$ tends to infinity the ratio $[\dim H/\dim B]$ tends to zero and the difference $[\dim B - \dim H]$ tends to infinity. Indeed,

$$[\dim H/\dim B] \leq 1/(N - 1) \quad \text{and} \quad [\dim B - \dim H] \geq (N - 1)2^N + 1 \quad (13)$$

### Appendix

**Lemma 1**  
Fix any integer $N \geq 2$ and let $\{z_i\}_{i=1}^N$ be any sequence of real numbers such that $z_i \geq 2$ for each $i = 1, \ldots, N$. If

$$W_N = N(\sum_{i=1}^N z_i) - \sum_{i=1}^N z_i \quad \text{and} \quad U_N = \sum_{i=1}^N z_i - 1,$$

then $W_N > U_N$, $W_N - U_N \geq (N - 1)2^N + 1$ and $U_N/W_N \leq 1/(N - 1)$. \hspace{1cm} (14)

**Proof:** First we will show that for each $N \geq 2$,

$$\sum_{i=1}^N z_i \leq \sum_{i=1}^N z_i.$$  \hspace{1cm} (15)

Fix any integer $N \geq 2$. Order the $N$ numbers $\{z_i\}_{i=1}^N$ and relabel if necessary so that $z_1 \geq z_2 \geq \cdots \geq z_N$. Define $S_k = \sum_{i=1}^k z_i$ and $P_k = X_{i=1}^k z_i$. Then $S_1 = z_1 = P_1$ and if $S_k \leq P_k$, then,

$$S_{k+1} = S_k + z_{k+1} \leq S_k + z_k \leq 2S_k \leq z_{k+1} \cdot S_k \leq z_{k+1} \cdot P_k = P_{k+1}.$$

Hence, by induction, (15) holds for each $N$. This, in turn, implies that for $N \geq 2$, $W_N - U_N = (N - 1)(\sum_{i=1}^N z_i) - \sum_{i=1}^N z_i + 1 \geq (N - 2)(\sum_{i=1}^N z_i) + 1 \geq (N - 1)2^N + 1$, from which the first two inequalities of (14) follow. Furthermore, $U_N/W_N = [P_N - 1]/[NP_N - S_N] \leq P_N/[NP_N - P_N] = 1/[N - 1]$.
